

## Syntax

```
e ::= x
    | \x -> e
    | e1 e2
```

- Programs are *expressions* or  $\lambda$ -terms
- Variable*: **x**, **y**, **z**
- Abstraction*: (aka nameless function definition)  $\backslash x \rightarrow e$  means “for any **x**, compute **e**”; **x** is the *formal parameter*, **e** is the *body*
- Application*: (aka function call) **e1 e2** means “apply **e1** to **e2**”; **e1** is the *function* and **e2** is the *argument*
- Syntactic Sugar*: convenient notation used as a shorthand for valid syntax

```
-- instead of:      we write:
\ x -> (\ y -> (\ z -> e))  \ x -> \ y -> \ z -> e
\ x -> \ y -> \ z -> e      \ x y z -> e
((e1 e2) e3) e4           e1 e2 e3 e4
```

- Scope of a variable* The part of a program where a *variable is visible*
- In the expression  $\backslash x \rightarrow e$ 
  - x** is the newly-introduced variable
  - e** is the *scope* of **x**
  - Any occurrence of **x** in  $\backslash x \rightarrow e$  is *bound* (by the *binder*  $\backslash x$ )
  - An occurrence of **x** in **e** is *free* if it is **not bound** by an enclosing abstraction
- Free Variables*: A variable **x** is *free* if there exists a free occurrence of **x** in **e** (not bound as a formal)
- Closed Expressions*: if **e** has no free variables it is *closed*
- $\alpha$ -step (renaming formals): we can rename a formal parameter and replace all its occurrences in the body
- $\beta$ -step (aka function call)
  - $(\backslash x \rightarrow e1) e2 =b> e1[x := e2]$
  - $e1[x := e2]$  means “**e1** with all free occurrences of **x** replaced with **e2**”
- Computation is **search and replace**: if you see an *abstraction* applied to an argument, take the *body* of the abstraction and replace all free occurrences of the *formal* by that argument
- Normal Forms*:
  - A *redex* is a  $\lambda$ -term of the form  $(\backslash x \rightarrow e1) e2$
  - A  $\lambda$ -term is in *normal form* if it contains no redexes
- Evaluation*:
  - A  $\lambda$ -term **e** evaluates to **e'** if there is a sequence of steps

```
e =?> e_1 =?> ... =?> e_N =?> e'
```

- each  $=?>$  is either  $=a>$  or  $=b>$  and  $N >= 0$
- e'** is in normal form
- e1 ==> e2**: **e1** *reduces* to **e2** in 0 or more steps
- e1 ==> e2**: **e1** *evaluates* to **e2**
- $\Omega$ :  $(\backslash x \rightarrow x x) (\backslash x \rightarrow x x)$
- Recursion*: Fixpoint Combinator

```
FIX STEP
==> STEP (FIX STEP)
```

- $\text{FIX} = \backslash \text{stp} \rightarrow (\backslash x \rightarrow \text{stp } (x x)) (\backslash x \rightarrow \text{stp } (x x))$
- Quicksort in Haskell*

```
sort :: [a] -> [a]
sort [] = []
sort (x:xs) = sort ls ++ [x] ++ sort rs
  where
    ls = [ l | l <- xs, l <= x ]
    rs = [ r | r <- xs, x < r ]
```

- Functions in Haskell*
  - Functions are *first-class values*
  - can be *passes as arguments* to other functions
  - can be *returned as results* from other functions
  - can be *partially applied* (arguments passed *one at a time*)
- Top-level bindings*:
  - Things can be defined globally
  - Their names are called *top-level variables*
  - Their definitions are called *top-level bindings*

## Equations and Patterns

```
pair x y b = if b then x else y
fst p      = p True
snd p      = p False
```

- A single function binding can have multiple equations with different *patterns* of parameters
- The first equation whose pattern matches the actual arguments is chosen
- Referential Transparency* means that a variable can be defined *once per scope* and *no mutation is allowed*; the same function always evaluates to the same value
- Local variables* can be defined using a **let** expression

```
sum 0 = 0
sum n = let n' = n - 1
        in n + sum n'
```

- Syntactic sugar for nested **let** expressions:

```
sum 0 = 0
sum n = let
        n'      = n - 1
        sum'    = sum n'
        in n + sum'
```

- If you need a variable whose scope is an equation, use the **where** clause instead:

```
cmpSquare x y | x > z = "bigger :)"
               | x == z = "same :|"
               | x < z = "smaller :("
  where z = y * y
```

- Types*:
  - In Haskell every expression either *has a type* or is *ill-typed* and rejected at compile-time
  - Types can be annotated using **::**

```
haskellIsAwesome :: Bool
haskellIsAwesome = True
```

- Functions have *arrow types*
- $\backslash x \rightarrow e$  has type **A**  $\rightarrow$  **B**
- If **e** has type **B** assuming **x** has type **A**
- A *Combinator* is a function with *no free variables*
- Lists*:
  - A list is either an *empty list*: **[]**
  - Or a *head element* attached to a *tail list*: **x:xs**

```
[]          -- A list with zero elements
1:[]        -- A list with one element
(:) 1 []    -- A list with one element
1:(2:(3:(4:[]))) -- A list with four elements
1:2:3:4:[]  -- Same thing
[1,2,3,4]   -- Syntactic sugar
```

- []** and **:** are called the list *constructors*
- A list has type **[A]** if each one of its elements has type **A**
- Pairs*: the constructor is **(,)**

```
myPair :: (String, Int)
myPair = ("apple", 3)
```

- Record Syntax*:
  - Instead of:

```
data Date = Date Int Int Int
```

- You can write:

```
data Date = Date {
  month :: Int,
  day   :: Int,
  year  :: Int
}
```

- Use the field name as a function to access part of the data:

```
deadlineDate = Date 1 10 2019
deadlineMonth = month deadlineDate
```

- Building data types:
  - Product* types (each-of): a value of **T** contains a value of **T1** and a value of **T2**
  - Sum* types (one-of): a value of **T** contains a value of **T1** or a value of **T2**
  - Recursive* types: a value of **T** contains a *sub-value* of the same type **T**
- Pattern Matching*:

```
html :: Paragraph -> String
html (Text str)      = ...
html (Heading lvl str) = ...
html (List ord items) = ...
```

- Match for arbitrary data types
- Dangers: *missing* or *overlapped* patterns
- Pattern matching expression

```
html :: Paragraph -> String
html p =
  case p of
    Text str      -> ...
    Heading lvl str -> ...
    List ord items -> ...
```

- The **case** expression has type **T** if every output expression has type **T** and the input is a valid pattern for the type; the input expression is called the *match scrutinee*
- Tail Recursion*: The recursive call is the *top-most* sub-expression in the function body; no computations allowed on recursively-returned body; the value returned by the recursive call is the value returned by the function
- Tail-recursive factorial:

```
loop acc n
  | n <= 1 = acc
  | otherwise = loop (acc * n) (n - 1)
```

- Tail recursive calls compile to fast loops automatically
- The *Filter* pattern:

```
filter :: (a -> Bool) -> [a] -> [a]
filter f [] = []
filter f (x:xs)
  | f x = x : filter f xs
  | otherwise = filter f xs
```

- Higher-order function which takes function **f** and a list as arg
- For each element **x** in the list, if **f x == True** then **x** will be in the output list
- The *Map* pattern:

```
map :: (a -> b) -> [a] -> [b]
map f [] = []
map f (x:xs) = f x : map f xs
```

- Higher order function which takes a function **f** and a list as arg
- For each element **x** in the input list, **f x** will be in the output list
- The *Fold-Right* pattern:

```
foldr :: (a -> b -> b) -> b -> [a] -> b
foldr f b [] = b
foldr f b (x:xs) = f x (foldr f b xs)
```

- Higher order function which recurses on the tail
- Combines result with the head in some binary operation
- len** = **foldr**  $(\backslash x n \rightarrow 1 + n)$  0
- sum** = **foldr**  $(\backslash x n \rightarrow x + n)$  0
- cat** = **foldr**  $(\backslash x n \rightarrow x ++ n)$  ""
- The *Fold-Left* pattern:

```
foldl :: (a -> b -> a) -> a -> [b] -> a
foldl f b xs = helper b xs
  where
    helper acc [] = acc
    helper acc (x:xs) = helper (f acc x) xs
```

- Higher order function uses a helper function with an extra accumulator argument
- To compute the new accumulator, combine the current accumulator with the head using some binary operation

- Useful HOFs:

- Flip**: flips the order of the input args

```
flip :: (a -> b -> c) -> b -> a -> c
```

- Compose**: compose functions

```
(.) :: (b -> c) -> (a -> b) -> a -> c
```

- Libraries will implement **map**, **fold**, **filter**, etc on its collections

```
